

# Back to the `point` class

---

- ▶ **Point is a very useful class**
  - ▶ More generally, *vector*
  - ▶ Vectors are the basis for all *spatial* simulations
    - ▶ 2d, 3d and even higher dimensions that we can't easily visualize
- ▶ **For simplicity, we'll stick with 2d**
  - ▶  $x, y$  gives a direction and distance
  - ▶ Starting from  $(0,0)$ , it specifies a point
  - ▶ But it could just as easily specify movement from a point
    - ▶ Adding vectors is just adding  $x$  and  $y$
  - ▶ Some examples...

# A Useful `vector` class

---

- ▶ **Simple, general and flexible**
  - ▶ 2 data members `x` and `y`
- ▶ **Methods for all the basic arithmetic operations**
  - ▶ These should all return a new vector (non-mutating)
  - ▶ `add(other_vector)`
  - ▶ `subtract(other_vector)`
  - ▶ `multiply(scalar)` # scalar is a number, not a vector
  - ▶ `magnitude()` # the length of the vector
  - ▶ `normalized()` # the same vector, with length one

# A Useful *vector* class

---

- ▶ Starting class to work with:

```
class vector:  
    def __init__(self):  
        self.x = 0  
        self.y = 0
```

# A Useful *vector* class

---

- ▶ **First, let's write a normal function that adds two vectors**
  1. Pass in two vectors as parameters
  2. Create a new local variable vector inside
  3. Assign the new vector  $x$  to the sum of the other two  $x$
  4. Assign the new vector  $y$  to the sum of the other two  $y$
  5. Return the new vector

# A Useful *vector* class

---

- ▶ First, let's write a normal function that adds two vectors

```
def add_vectors(v1, v2):  
    sum = vector()  
    sum.x = v1.x + v2.x  
    sum.y = v1.y + v2.y  
    return sum
```

- ▶ Called like:

```
add_vectors(position, movement)
```

# A Useful `vector` class

---

- ▶ Methods are just functions that are part of a class
- ▶ The big difference!
  - ▶ Methods are *called on* an object of that class
  - ▶ Function: `add_vectors(position, movement)`
  - ▶ Method: `position.add_vectors(movement)`
- ▶ Think of it as telling the object to do something
  - ▶ E.g. “hey position, add movement to yourself”

# A Useful `vector` class

---

- ▶ The method version:

- ▶ Is defined inside the class
- ▶ Replaces the first parameter (one of the vectors) with `self`
  - ▶ `self` is a reference to the object the method is called on

```
def add_vectors(self, v2):  
    sum = vector()  
    sum.x = self.x + v2.x  
    sum.y = self.y + v2.y  
    return sum
```

- ▶ Called like:

```
position.add_vectors(movement)
```

- ▶ Note that you only pass in the parameters *besides* `self` (`v2` here)

# A Useful *vector* class

---

- ▶ **Could also do the self-mutating version**
  - ▶ Changes itself rather than returning a new vector object

```
def add_vectors(self, v2):  
    self.x = self.x + v2.x  
    self.y = self.y + v2.y  
    # no return necessary
```

# That constructor

---

- ▶ We started our class with a *constructor*

- ▶ A method that is called automatically whenever we create an object of the class
- ▶ The special name `__init__` tells Python to call this automatically

```
def __init__(self):  
    self.x = 0  
    self.y = 0
```

- ▶ This is called the *default constructor*

# That constructor

---

- ▶ Alternatively, we could have a constructor that takes additional parameters

```
def __init__(self, x, y):  
    self.x = x  
    self.y = y
```

- ▶ This *parameterized constructor* allows us to specify the initial values, like:

```
v = vector(3, 4)
```

- ▶ (note that you don't pass in self, it's already there!)

- ▶ The one we did before, with no additional parameters, is the *default constructor*

```
v = vector()
```

---
